262 NOTES

Prashad (1932) is of opinion that the Lamarckian species, *P. lotorium* is based on slightly different shells of his earlier species, *P. macroptera* and that these two species are therefore synonymous. The configuration of the auricles alone, which is subject to variation according to size as revealed by the examination of shells from the Andamans, is of little significance in determining the species. The shells from the Andaman sea and from the Gulf of Mannar are referable to *Pteria penguin* (Röding).

P. penguin is a widespread species and the extent of its distribution is from 'Australia to Madagascar' (Prashad 1932). The species is common throughout the Indo-Pacific region. It abounds off the coasts of Japan and nearby islands where it is successfully employed by the Japanese technicians for culturing large sized hemispherical pearls.

The writer has great pleasure in offering his thanks to Dr. S. Jones for the interest he has shown in the preparation of this note and to Shri K. G. Nambiar for taking the photographs of the shells.

A NOTE ON THE OCCURRENCE OF THE BLUE GREEN ALGA APHANOCAPSA LITTORALIS HANSG, VAR. MACROCOCCA HANSG. CAUSING COLOURATION OF THE SAND AND ITS RELATION WITH THE TIDES

Though there are many reports, from various parts of the world, about organisms inhabiting intertidal sands causing colouration and the tidal rhythm of the causative organisms, little attention seems to have been paid to these in India. Dixit (1936) reported the occurrence of Aphanocapsa littoralis var. macrococca on the Chowpathy sea-shore in Bombay but no information has been given about its relation with the tide. Recently, Ganapati, Rao and Rao (1959) reported the tidal rhythms of some diatoms and dinoflagellates inhabiting the intertidal sands of the Visakhapatnam Beach. The present note is based on the occurrence of a blue-green alga causing a green colouration of the sand at Karwar Beach in the North Kanara Coast.

NOTES 263

At low tide, during February-April and sometimes also in August and October, the intertidal zone of the sandy beach is often found to exhibit widespread dull green colour which develops under the brilliance of the sun. Examination of this coloured sand revealed the presence of dense populations of *Aphanocapsa littoralis* Hansg, var. macrococca Hansg, adhering to the sand grains with the help of their mucilaginous envelope.

Individual cells varied from 3.5-6.0 μ in diameter and isolated individual cells kept in watch glasses showed active wriggling movement when agitated. Kept undisturbed, the cells clustered around the water margin in groups and adhered to the glass and the grains of sand.

During day time at low tide these organisms appear in thick, evenly spread, green patches in the sandy beach. At the time of high tide these green patches disappear and therefore, the occurrence of the colour seems to synchronize with the tidal periodicity.

It is observed, that no such colour develops in the beach when the low tide is exclusively confined to the night. However, the green patches that develop during day time at low tide continue to exist in the beach at night as long as that low tide remains. It shows that the development of the colour has some relation to light also and a more detailed study on this will throw light on the probable causes of this behaviour of the alga.

I am grateful to Dr. R. Prasanna Varma for identifying the alga. I wish to express my sincere thanks to Dr. R. Raghu Prasad, Research Officer (Marine Biology), Central Marine Fisheries Research Institute, Mandapam Camp, for helpful criticism.

A VIVIPAROUS NEMATODE, PHILOMETRA SP. IN THE OVARIES OF OTOLITHUS ARGENTEUS (CUVIER)

While engaged in the study of spawning periodicity of certain teleostean fishes of Mangalore area, a parasitic nematode was observed in the ovary of Otolithus argenteus (Cuv.). The fish measuring 203 mm. in total length and harbouring the parasite within its gonads appeared to be normal in its external body features. The parasitised ovaries of the fish presented dark red colouration and through the semi-transparent ovarian walls some of the coils of the parasite within could be seen. Except in the anterior one-third of the left ovary and the apical region of the right one where a few ovarian immature eggs measuring 0.019 to 0.134 mm. were found, the rest of the space in both the ovaries was occupied by the coils of the parasite. When the coils were unravelled, it was observed that in the region of the oviduet the part of the body of the parasite lying within the left ovary was continuous with that lying in the right ovary.
